ABSTRACT

A common practice in assessment is to have a shared stimulus followed by a number of questions. One might doubt the usual assumption of standard item response theory of local item independence between items in these cases. Such a violation might contribute to the misfit of a unidimensional model, as an anticipated violation of conditional independence within these item bundles or testlets; one might consider a unidimensional model that incorporates local dependence. On the other hand, violations of local independence in a unidimensional model might in some cases be more satisfactorily solved with a multidimensional model with local independence. Even a multidimensional model with local dependence might be entertained. This paper discusses the application of Item Bundle Model developed by Wilson and Adams that can take account of multidimensionality and item dependence simultaneously. The use of the model is illustrated in the framework of the University of Michigan’s BioKids 2002-2003 Fall Assessment.

Key words: item bundles, local item independence, multidimensional random coefficients multinomial logit (MRCML) model
Assessing Local Item Dependence in Building Explanation Tasks

An Application of the Multidimensional Random Coefficients Multinomial Logit Item Bundle Model
ACKNOWLEDGEMENTS

This work was supported by the National Science Foundation under grant REC-0129331 (PADI Implementation Grant). We would like to thank Nancy Butler Songer and Amelia Wenk Gotwals of the BioKIDS project for permission to use the data in the example, and their time, patience, and insights in helping us understand the substantive aspects of the modeling described here. We are grateful to Larry Hamel and Cathy Kennedy for lots of help along the way.
INTRODUCTION

The cornerstone of item response theory (IRT) is the assumption of *local independence*, which posits that an examinee’s response to a given test item depends on an unobservable examinee parameter but not on the identity of or responses to other items the examinee may have been presented (Lord, 1980). More formally, responses to test items are conditionally independent, given item parameters and . This is a strong assumption. In some measurement situations, especially performance assessment, the items are grouped into bundles marked by shared common stimulus materials, common item stems, or common item structures. These situations call into question the assumption of local independence (Wilson & Adams, 1995). For example, item bundles are desirable in mathematics and science performance assessments because they reflect real life situations in which subproblems are interrelated and work is organized in steps. Solving one item in a bundle might increase the chances of solving the next. Even if a unidimensional model is appropriate for modeling responses, these interrelationships within clusters of related tasks constitute conditional dependence.

Moreover, sometimes additional and different content knowledge or skills are required in each problem step. In such cases the resulting local dependence in a unidimensional model may be better thought of as model misfit, as a multidimensional model would be a more appropriate and reduce or eliminate conditional dependence. It is useful, therefore, to distinguish between local dependence and departures from unidimensionality. This paper proposes the application of Item Bundle Multidimensional Random Coefficients Multinomial Logit Model (MRCMLM; Adams, Wilson, & Wang,
1997) to check whether there is still dependence after taking dimensionality into consideration.

THEORETICAL FRAMEWORK

Much previous work on local independence exist in educational and psychological testing literature. Rosenbaum (1988) christened the concept of ‘item bundle’ to denote item subsets sharing common test stimulus and the idea of ‘bundle independence’, which is that bundle response patterns rather than individual items are conditionally independent given latent student variables. Wainer and Kiely (1987) used their notion of a “testlet”, and suggested taking each testlet as an ordered polytomous item and using an ordered item response model to analyze the bundled scores. Wilson (1988) used the partial credit model and the rating scale model in a similar way. In order to provide the flexibility of customizing models for particular test situations, Wilson and Adams (1995) described an alternative approach to look at the bundle itself as source of data, and used the random coefficients multinomial logit model (RCML; Adam & Wilson, 1992) to investigate the violation of the conditional independence assumption. From nonparametric and factor analytic perspectives on IRT, a significant amount of research (e.g. Stout, 1987; Zhang, 1996; and Zhang & Stout, 1999) has been done to determine when proficiency unidimensionality is violated, estimate the degree of dependence, and assess the number of latent factors. Recently, from a Bayesian parametric point of view, Bradlow, Wainer and Wang (1999) modified standard IRT models to include an additional random effect for items nested within the same testlet to account for shared variation of items within testlets.
When a local dependence problem occurs in a set of test items that measures more than one latent ability, on the one hand, the violation of local item independence might suggest the existence of a new latent trait because of misfit of unidimensional model. On the other hand, the interdependence of the items might cause the dimensions to appear highly correlated, and thus the multidimensional analysis will provide the misleading results that only one dimension needs to be modeled. Is there dependence, dimensionality, or both?

By applying the concept of item bundles to multidimensional analysis, an item bundle model nested in a multidimensional random coefficients multinomial logit (MRCML) model (Adams, Wang & Wilson, 1997) provides us opportunity to take account of multiple dimensions and item dependence simultaneously, by carefully modeling the expected patterns of dependence based on substantive knowledge about the structures and the demands of the tasks. Since local independence can always be achieved simply by increasing dimensionality as needed, the distinction is not mathematical. As our examples show, the investigation is instead an interplay between alternative mathematical models and what is known substantively about the contents and the forms of tasks.

The present paper briefly reviews the item bundle MRCML model, and then works through an example of a bundle and dimensionality framework using data from the project *BioKids: Kids Inquiry of Diverse Species*. Ideas are illustrated in some detail with two complex tasks, which required answering questions about a substantive situation then providing a scientific explanation of the situation. We focused on two item bundles, analyzing one at a time. For a given bundle, first under the unidimensional model, we fit the items bundled to model conditional dependence (i.e., bundle subitems in the task that
is in focus) and again not bundled (maintaining the assumption of conditional independence among the subitems in that task), while keeping the same model for all the other items or item bundles in the test. This comparison allows for checking whether dependence exists in the bundle while positing unidimensional proficiency. Next, an analogous analysis was pursued with a multidimensional model suggested by the content demands of the items, to see whether dependence still existed after we take the issue of dimensionality into consideration. Structurally similar item bundles are built and analyzed in the same way as in the unidimensional comparison.

THE MODEL

The Item Bundle Multidimensional Random Coefficient Multinomial Logit Model

The MRCML model is a multidimensional extension of the random coefficients multinomial logit model, which can be applied to multidimensional polytomous test items. This paper will focus on item bundles. Suppose there is a set of $C$ bundles; $I_c$ is the number of items in each bundle and $K_c$ is the total number of distinct response patterns in item bundle $c$, the number of all combinations of responses across all items in the bundle. For example, if a bundle is composed of one dichotomous item and one three-category item, there can be six distinct response patterns: $(0,0)$, $(0,1)$, $(0,2)$, $(1,0)$, $(1,1)$ and $(1,2)$. The probability of one particular response pattern $j$ (e.g., $j$ is the index over possible response patterns in a bundle) of bundle $c$ can be modeled as
\[ P(X_C = j | \tilde{\Theta}, A_C, B_C, \tilde{\Xi}) = \frac{\exp(b_{cj} \tilde{\Theta} + a_{cj} \tilde{\Xi})}{\sum_{k} \exp(b_{ck} \tilde{\Theta} + a_{ck} \tilde{\Xi})} \]  

(1)

Where: \( X_C = j \) is the person’s response in category \( j \) of item bundle \( c \);

1. Vector \( \tilde{\Theta} = (\theta_1, \theta_2, \ldots, \theta_D)' \) defines a D-dimensional latent trait (if we take a one-dimensional model as a special case of MRCML model, \( \theta \) is a scalar in the equation);

2. The scoring vector \( b_{cj} = (b_{cj1}, b_{cj2}, \ldots, b_{cjD})' \) specifies the “performance level” to bundle response pattern \( j \) of bundle \( c \). It can be collected into a bundle scoring sub-matrix \( B_C = (b_{c1}, b_{c2}, \ldots, b_{ck})' \), for bundle \( c \), and further into a test scoring matrix \( B = (B_1', B_2', \ldots, B_C') \). The bundle scoring sub-matrix allows different numbers of categories for different item bundles and thus affords the possibility for the model to calibrate both dichotomous and polytomous item bundles simultaneously;

3. Vector \( \tilde{\Xi} = (\xi_1, \xi_2, \ldots, \xi_p)' \) is used to model the \( p \) bundle response patterns, which can be characterized as bundle difficulty, bundle step difficulty, etc;

4. The design vector \( a_{cj} = (a_{cj1}, a_{cj2}, \ldots, a_{cjp})' \) relates each observed response pattern to item bundle parameter vector \( \tilde{\Xi} \), which can be gathered into bundle sub design matrix \( A_C = (a_{c1}, a_{c2}, \ldots, a_{ck})' \), with \( p \) columns, and which in turn can be gathered into the test design matrix \( A = (A_1', A_2', \ldots, A_c')' \); the design matrix determines how the
model is specified for a collection of items as a whole.

As will be shown, appropriate choices of design matrices $B$ and scoring matrices $A$ allow us to express, and then compare, different conjectures about the nature of dependence and dimensionality affecting responses to items within and between bundles.

Bundle Independence

Suppose there is a set of $C$ bundles and $U_{nc}$ is person $n$’s response pattern for bundle $c$. Bundle independence can be defined in the following way:

$$P(U_{n1}, U_{n2}, K, U_{nc} | \theta_n, \xi) = \prod_{c=1}^{C} P(U_{nc} | \theta_n, \xi),$$

(2)

Following Rosenbaum’s idea, bundle independence means that examinee $n$’s response pattern $U_{nc}$ on a set of items in a bundle are independent with those in other bundles given latent proficiency parameters $\theta_n$ and item bundle parameters $\xi$.

EXAMPLE

Data

The data set explored in this paper is from BioKids Fall 2003 Pretest Assessment. Totally, 220 students take the test. The *BioKids: Kids’ Inquiry of Diverse Species* project at the University of Michigan (Prof. Nancy Butler Songer, Principal Investigator) is developing, testing, and organizing inquiry-focused, technology-rich science programs in biodiversity, weather, motion and other content areas to span from 5-8th grades. The assessment system includes tasks formulated around three different inquiry skills at different levels of complexity and scoring rubrics used to capture students’ knowledge of
both content and inquiry skills. In the current BioKids Fall 2003 Assessment, there are totally 19 items with three types of format: Multiple choices, Fill-in-blank, and Open-ended. Within these items, 16 focus on Biodiversity and the other 3 cover Simple Machines content. Since the development of sensitive inquiry assessment instruments is the central focus of the project, the assessment tasks are designed to evaluate student’s understanding of inquiry thinking beyond content knowledge. There are four kinds of inquiry skills addressed in this assessment, including Hypothesis/Predictions, Explanations, Interpreting Data, and Re-express data. Each task may be associated with content, inquiry skills, or both. The two tasks addressed in the data analysis are shown in Appendix A.

Analysis Design

In the current analysis, we focus on the first 16 Biodiversity items and address 6 bundles in total. In order to examine the dependence and dimensionality issues, we found two item bundles (BioKids04 and BioKids05) with similar structures, each of them having a claim item and an evidence item. They can be thought of a special type of item bundle. At first, student is asked to make a claim using certain Biodiversity content knowledge; in the subsequent evidence part, the student is asked to explain the reasoning used to produce the previous answer where Biodiversity content knowledge and specified inquiry skill are both required. For both examples, the claim item is dummy coded with “0” representing for “incorrect” and “1” as “correct” and the evidence item is coded as (0,1,2) with “0” representing for “incomplete” answer, “1” as “partial correct” answer and “2” as “complete” answer. The Conquest computer program (Adams, Wilson &
Wang, 1997) was used to analyze the item bundle MRCML model. The dimensionality and dependency problems are addressed as follows:

**Dimensionality.** Three kinds of models are fitted to the data set: unidimensional model, two-dimension model and five-dimension model. First, if we regard content combined with inquiry skill as one latent trait, a one-dimensional model is being applied. Then, taking all kinds of inquiry skills as one dimension and the content knowledge as another dimension, we use two-dimension model. Some items have been identified by the BioKIDS content experts as depending mainly on content knowledge, others as depending mainly on inquiry skill, and others as requiring both. These judgments determine the \( a \) vectors for each item in the MRCMLM scoring matrix. Finally, if we associate each item with its specified inquiry skill, a five-dimension model with one content and four inquiry skills is fit to the data. For a given conjecture about local dependence within bundles, the Design Matrices of these three dimensionality models are all the same; the only differences are the Scoring Matrices, which relate the observed response or responses patterns to the latent trait(s).

**Dependence.** In order to address the dependence issue carefully, we compare two models concerning items within claim/evidence tasks: Not Bundled model vs. Bundled model, under three kinds of dimensionality situations separately. (Recall Bundled = locally dependent; not bundled = independent.) As to the Not Bundled model: focusing on one item bundle, for example Biokids04, we only do not bundle this item. This means we take the claim item and evidence item of this bundle as two separate items, and bundle all the others in the test that have been proposed as candidates to be bundled. Table 1 and Table 2 show the design matrix and scoring matrix of a claim item and
LOCAL DEPENDENCE - 13 -

evidence items under conditions of the three dimensions. Note that in the 2- and 5-
dimensional models, the claim item is posited to depend only on the content skill, while
the evidence item is posited to depend on both the content and inquiry dimensions.

[[Table 1: Parameterization of Not Bundled Model of Biokids04 (claim)]]

[[Table 2: Parameterization of Not bundled Model of Biokids04 (Evidence)]]

Whereas, for the bundled model under the same unidimensional condition, we bundle
in the same way all the other items that conjectured to be bundled but now including the
one we are interested in. For the same example Biokids04, if we bundle the claim item
and evidence item, there will be six possible response patterns with (0,0) as a reference
pattern. We recode them using 0– 5. The design matrix and scoring matrix of this bundle
are shown in Table 3.

[[Table 3: Parameterization of Bundled Model of Biokids04]]

Obviously, the bundled model is more complex than the not bundled model because
there are more item bundle parameters. Intuitively, the difference between the models is
this: Under the not-bundled model, the difficulty of going from 0 to 1, then 1 to 2 on the
evidence item is the same no matter what the response to the claim item was. These
difficulty parameters are $b_{e=1}$ and $b_{e=2}$. Under the bundled model, the increments in the
evidence steps can be different if claim=0 or claim=1, as indicated by $b_{e|k=0}$ and $b_{e|k=0}$,
versus $b_{e|k=1}$ and $b_{e|k=1}$.

After we finished defining the whole test design matrix and test scoring matrix, item
parameters of those two customized models can be estimated in Conquest. Therefore we
can substitute the results into equation (1) for the bundled model to calculate the
probability of each response pattern. As to the not bundled model, assuming the response
to the claim item and that of evidence item are independent, the probability that an examinee get a response $j$ for claim and a response $k$ for the evidence is just the product of the two probabilities, or

$$p(X_c = k)p(X_e = j) = \frac{\exp(\hat{b}_c \hat{\theta} + \hat{a}_c \hat{\xi} + \hat{b}_e \hat{\theta} + \hat{a}_e \hat{\xi})}{\sum_{c=0}^{1} \exp(\hat{b}_c \hat{\theta} + \hat{a}_c \hat{\xi}) * \sum_{e=0}^{1} \exp(\hat{b}_e \hat{\theta} + \hat{a}_e \hat{\xi})}$$

(3)

Then, in order to exam whether not-bundled model or bundled model fit the data, or in other words, to gauge the degree of local dependence, a Chi-square test can be used to compare observed and predicted response pattern counts. Two contingency tables corresponding to the bundled and not bundled models have been constructed over the same six cells: (0,0) (0,1) (0,2) (1,0) (1,1) (1,2), with the first element is associated with the response to the claim and the second with the response to the evidence. The observed proportions of examinees with correct answers in each cell are reported in the ConQuest initial analysis results. The predictions for each cell are obtained by using trait and item parameter estimates from ConQuest output as shown below (calculations were carried out using the computer program Mathematica, Wolfram, 2003). All item and person parameters of different models used are provided in Appendix B–D.

Assuming theta is normally distributed, the predicted proportion in cell $r$ under the bundled model is obtained as:

$$E_r = \int p(x = j|\hat{\theta})p(\hat{\theta})d(\hat{\theta}) = \frac{1}{\sqrt{(2\pi)^r|\Sigma|}} \int \frac{\exp(-\frac{1}{2} (x - \mu)\Sigma^{-1}(x - \mu) + \hat{b}\hat{\theta} + \hat{a}\hat{\xi})}{\sum_{c=1}^{K} \exp(\hat{b}\hat{\theta} + \hat{a}\hat{\xi})} d(\hat{\theta})$$

(4)
For not bundled model, the prediction is obtained as:

\[
E_r = \int p(x_c = k)p(x_e = j)p(\bar{\theta})d(\bar{\theta}) = \frac{1}{\sqrt{(2\pi)^*|\Sigma|}} \int \exp\left(-\frac{1}{2}(x - \mu)'\Sigma^{-1}(x - \mu) + b_c'\bar{\theta} + a_c'\bar{\xi} + b_e'\bar{\theta} + a_e'\bar{\xi}\right) d(\bar{\theta})
\]

(5)

Under the one-dimensional solution, theta is a scalar representing an overall proficiency in the collection of tasks. Under the two-dimensional situation, two thetas are bivariate normally distributed, and the expected proportions are integrated over the joint range of both dimensions. Under the five-dimensional solution, each item requires content knowledge and specific inquiry skill(s). For example, BioKids04 is associated with Biodiversity content knowledge and the inquiry skill of Building Explanation from Evidence. Therefore, the expected proportions are dually integrated over the bivariate normal distribution of just these two thetas. The resulting contingency tables for Item 4 and Item 5 are listed in Appendix E. The expression used below to compute a goodness of fit Chi-square for each model is as follows:

\[
\chi^2 = \sum_r \left(\frac{n_r - \hat{n}_r}{\hat{n}_r}\right)^2
\]

(6)

Letting \(n_r\) be the observed frequency for each response category \(r\); based on a total of \(N\) observations, the expected frequency for the \(r\)th response category is

\[
\hat{n}_r = N * E_r
\]

(7)

Where \(E_r\) is the expected proportion for each response category, which is computed in equation 4 or 5 as appropriate.

We were first interested in investigating whether conditional dependence exists
between claim and evidence parts under unidimensional situation, looking at each of the two targeted items one at a time? Then what happens when we add more latent traits that are suggested by what we know about the items substantively? Items that are locally dependent in a lower-dimensional model may or may not be locally dependent in a higher dimensional model that is suggested by the substantive analysis of the items’ demands.

Results

The Chi-square values for BioKids04 and BioKids05 are listed in Table 4 and Table 5 separately. For evaluations, the critical Chi-square value is 15.086 with degrees of freedom of 5 and significant level of .010. The results for Item 4 are shown in Table 4.

[[Table 4: Chi-Square results of Biokids04]]

For BioKids Item 4, under the one-dimension solution, since the Chi-square values are all less than the critical value of 15.086, both the Bundled and not Bundled models can be considered to fit the data adequately. Shifting attention to the two-dimensional solution, we can see that Chi-square values decreased especially for Bundled model, which suggests there does exist conditional dependence between the claim and evidence items in this bundle. Comparison with the one-dimensional result slightly indicates a better fit of the two-dimensional over the unidimensional model. When we move from two-dimension model to five-dimension model, the Chi-square value does decrease but not a lot, suggesting that the evidence part of this bundle only requires a general inquiry skill in the model as opposed to specific ones such as the Building Explanation from Evidence dimension associated with this item. In all, the simplest model considered, namely unidimensional with conditional independence, proves satisfactory for this item.
The results for BioKids Item 5 are shown in Table 5. We can reach conclusion that the bundled model fits the data much better than the not bundled model for the one-dimension, two-dimension and especially five-dimension solutions. Obviously, dependence does exist in this case even after we take a detailed dimensionality issue into consideration.

[[Table 5: Chi-Square results of Biokids05]]

How could we get different results for these two items, even though they have similar structures? A number of possibilities exist. The dependence issue also related to the idiosyncratic features of the tasks. For example, for some items it may be virtually necessary to provide a correct answer to the claim, or more content related item, in order to provide a good explanation, whereas for other items one might be able to provide a good explanation despite having stumbled on the specifics of the claim. Therefore, the two subitems seem less dependent. Or if the examinees have general science knowledge, they may be able to get correct answers for the claim part but not evidence part.

For our example, the first reason seems more plausible. With Biokids04, students will choose insects group on their first glance because a fly looks more like insects than spiders. Thus, even without having a certain amount of Biodiversity knowledge (such as flies and insects both have wings, six legs and antennae, etc.), they may give the correct answer to claim part but not evidence part since the latter needs more specialized inquiry skills as well as deeper content knowledge. However, as to Biokids05, students won’t answer the claim item correctly if they don’t know that trees are habitat of squirrels and birds. In other words, more content knowledge is demanded in the claim part of
Biokids05 than that of Biokids04; the two parts are more interrelated in the bundle Biokids05, thus there is more evidence of local dependence.

Beyond the Chi-Square analysis, the Deviance results provided by ConQuest as a model-fit index are also of interest. Deviance is approximately \(-2\times\log \text{ likelihood}\) and a formal statistical test of relative fit of nested models can be undertaken by comparing the deviance of the two models. Table 6 lists the deviance information for all the models used in the analysis.

[[Table 6: Overall deviance results of bundled model and not bundled model under three dimensional situations]]

From the above table, on the one hand, we can see that the increases of deviances of the not bundled model vs. bundled model across three dimension situations for Item 4 are less than those of Item 5, which suggests a similar conclusion as the Chi-square analysis. The dependencies do seem to exist, especially for bundle BioKids Item 5.

On the other hand, using the deviance statistics for the three models can make the comparison of the relative fit of the unidimensional and multidimensional models. Since the one dimensional model is nested within the two and the two-dimensional model is nested within the five, the difference in the deviance between the two is distributed as approximately chi-square, with degree of freedom equal to the number of additional parameters in the more complex model. Having the same number of item parameters to estimate for a model with particular bundling configuration, the degree of freedom of our example is based on the differences caused by increasing of the number of dimensions. Since the thetas in each dimension are set to zero to identify the models, the increase in number of parameters is the number of additional variance and covariance elements.
Going from one to two dimensions adds two parameters; from two to five dimensions adds twelve.

For the one-dimension bundled model and the two-dimension bundled model, the difference in the deviance is 105.651, with two degrees of freedom. This is extreme statistically significant at the 0.01 level comparing to the critical value of $\chi^2_{(2,0.01)} = 9.21$, which means that two-dimension bundled model fits the data much better than one-dimension bundled model. However, as to the two-dimension bundled model vs. five-dimension bundled model, the difference in the deviance is 5.72, with 12 degrees of freedom. It is not statistically significant at the 0.01 level compared to the critical value of $\chi^2_{(12,0.01)} = 26.22$. The results tell us there are more than one dimensions in the assessment, and since the results are consistent under the different bundling options, the interdependence of the items does not cause misleading results of multidimensional analysis. In our example, the two-dimension bundled model with content knowledge as one dimension and an overall inquiry skill as another dimension fits the data satisfactorily.
DISCUSSION

When item response theory models are applied to test data with multi-part responses and mixtures of content demands, one has cause to investigate whether the assumptions on which the analysis is based are completely justified. This paper focuses on one of the main assumptions: the local independence. If the local independence assumption is not met, there is local dependence. In particular, we investigated situations that could involve both conditional dependence caused by a common problem situation and multidimensionality caused by different configurations of knowledge demands.

A multidimensional item bundle analysis suggest that the BioKids Fall 2003 Pretest exhibits item local dependence in at least one cluster of items based on a common stimulus situation. Taking dimensionality and idiosyncratic features of test format into consideration when expressing and testing various hypotheses about the nature of item dependence makes the analysis of local item independence more accurate and meaningful. Modeling such data using the MRCML item bundle model can deal with item dependence and dimensionality simultaneously, expressing and disentangling these sources of shared variation, thereby reduce distortions in item parameter estimates as well as proficiency estimates caused by ignoring these important features of patterns in data.

Appendix A

Two items of BioKids 2003 Fall Assessment

4. Shan and Niki collected four animals from their schoolyard. They divided the animals into Group A and Group B based on their appearance as shown below:

Group A: [Images of animals]

Group B: [Images of animals]

They want to place this fly in either Group A or Group B. Where should this fly be placed?

A fly should be in Group A / Group B

Circle one

Name two physical characteristics that you used when you decided to place the fly in this group:

(a) [Blank]

(b) [Blank]

Total = 3

(Claim) correct (1) – Group A

incorrect (0) – Group B, multiple circles or no response

(Data/Evidence) complete (2) – two correct responses with no incorrect responses

partial (1) – one correct response; or two correct responses with additional incorrect responses

incomplete (0) – other responses or no response

Correct Responses include:

• having six legs/how many legs
• having wings
• having three body parts
• being insects
• not being spiders
• having antennae
• spiders and insects are not in the same group

Explanations – Step 2

5. Using the graph below, predict which zone most likely has a tree in it and give one reason to support your prediction.

[Graph of schoolyard animals]

I think that zone ________ has a tree in it because...

1

2

Total = 3

(Claim)

Correct: Zone B

Incorrect: Zone A or blank

(Data/Evidence)

complete: (2) – Mentions both Animal (Bird OR squirrel) AND habitat function (live/found in trees, get food from trees, hide from predators in trees) with no incorrect responses

partial: (1) – Mentions EITHER Animal (Bird OR squirrel) OR habitat function (live in trees, get food from trees, hide from predators in trees); or mentions both animal and habitat function but with additional incorrect responses.

incomplete: (0) – other responses or no response

Disregard irrelevant responses related to “ants”

Interpreting Data – Step 2
